Abstract

In this paper we propose first steps towards calculating the energy shifts of confined Rydberg excitons in Cu₂O quantum wells, wires, and dots. The macroscopic size of Rydberg excitons with high quantum numbers \( n \) implies that already \( \mu \text{m} \) sized lamellar, wire-like, or box-like structures lead to quantum size effects, which depend on the principal Rydberg quantum number \( n \). Such structures can be fabricated using focused ion beam milling of cuprite crystals. Quantum confinement causes an energy shift of the confined object, which is interesting for quantum technology. We find in our calculations that the Rydberg excitons gain a potential energy in the \( \mu \text{eV} \) to \( \text{meV} \) range due to the quantum confinement. This effect is dependent on the Rydberg exciton size and, thus, the principal quantum number \( n \). The calculated energy shifts in the \( \mu \text{eV} \) to \( \text{meV} \) energy range should be experimentally accessible and detectable.

Keywords: Rydberg excitons, cuprous oxide, quantum wells

(Some figures may appear in colour only in the online journal)

1. Introduction

1.1. Rydberg excitons

Rydberg atoms build an important platform for quantum applications because of their long lifetimes and large dipole moments, allowing for the formation of long-range interactions and rendering them highly sensitive for external fields on a quantum level [1–7]. They feature many interesting properties, such as the generation of nonclassical photonic states [8–10], or the dipole blockade [11, 12], which can be used for optical switching and other quantum information processing applications [13–18]. However, their incorporation into the solid state remains difficult.

Rydberg excitons are the solid-state analog of Rydberg atoms. Due to the attractive Coulomb interaction between the conduction electron and the valence hole in a semiconductor, a quasiparticle called exciton can be formed as an excited electronic state of the crystal. This electron–hole pair is weakly bound and extends over many thousands of lattice unit cells, thus its interaction is screened by the static permittivity of the semiconductor (see figure 1(a)). Its energetic levels \( E_n \) lie within the semiconductor band gap \( E_g \), while the exciton binding energy \( E_b = \text{R}_y^*/(n - \delta_p)^2 \) increases with the principal quantum number \( n \) as \( 1/n^2 \):

\[
E_n = E_g - \text{R}_y^* \frac{1}{(n - \delta_p)^2}.
\]

\( \text{R}_y^* = \text{R}_y m_e/(\varepsilon^2 m_\text{h}) \) is the modified Rydberg constant in the semiconductor due to effective electron and hole masses, \( m_e \) and \( m_\text{h} \), which form a reduced mass \( m_r = m_e m_\text{h} / (m_e + m_\text{h}) \), \( \varepsilon \) is the background dielectric constant, and \( \delta_p \) the quantum defect for P-excitons.

This is in analogy to Rydberg atoms, where the outer electron orbits around the nucleus, following the hydrogen formula \( E_n = -\text{R}_y/n^2 \), with \( \text{R}_y \) being the Rydberg constant. Now, electron and hole orbit around each other and are termed Rydberg exciton, when being in quantum states with large principal quantum number \( n \geq 10 \). The total exciton energy, including its center-of-mass kinetic energy, is

\[
E_n = E_g - \text{R}_y^* \frac{1}{(n - \delta_p)^2} + \frac{\hbar^2 K^2}{2M}.
\]
These giant Rydberg excitons are very sensitive to external fields due to their huge polarizability (scaling proportional to $n^7$) [22] and can be easily trapped and positioned in the solid state system [23]. In order to use these giant, highly sensitive quantum objects for quantum technology [1, 2, 24–26], their basic behavior has recently been intensively investigated [27–35].

Excitons are decisive for semiconductor optical properties [36]. The electron–hole relative motion is on a large scale compared to interatomic distances. Therefore, in contrast to Rydberg atoms, which are described by a modified electron wave function only, the exciton wave function $\Phi^{exc}$ is given by the electron wavefunction $\phi^e$ times the hole wavefunction $\phi^h$ times an envelope wave function $\phi^{env}$:

$$\Phi^{exc} = \phi^e \times \phi^h \times \phi^{env}. \quad (4)$$

The envelope wave function describes the electron–hole relative motion, or the angular momentum quantum state, and can be expressed in spherical harmonics as $Y_l^m = \sqrt{1/4\pi}$ for S-excitons ($l = 0$) or $Y_l^l = \sqrt{3/4\pi} z/r$ for P-excitons ($l = 1$).

The exciton wave function obeys the two-particle Schrödinger equation (also known as Wannier equation)

$$\left( -\frac{\hbar^2}{2m_e} \nabla_e^2 - \frac{\hbar^2}{2m_h} \nabla_h^2 - \frac{e^2}{\varepsilon_0 |r_e - r_h|} \right) \Phi^{exc} = E \Phi^{exc}, \quad (5)$$

with indices $e$ and $h$ denoting electron and hole, respectively. Equation (4) can be rewritten in relative coordinates only, since the Coulomb term only affects the relative electron–hole coordinates. It then reads:

$$-\frac{\hbar^2}{2m_r} \nabla_r^2 - \frac{e^2}{\varepsilon_0 \varepsilon_r} \phi^{env}(r) = E_r \phi^{env}(r), \quad (6)$$

with the reduced exciton mass $m_r$ [37].

### 1.2. Quantum confinement

Rydberg excitons in cuprous oxide quantum wells have not yet been studied, although the concept of the related problem is well known. The problem can be described via potential well calculations. These have already been extensively performed for electrons and holes in semiconductors [38]. Mesoscopic spatial confinements of the order of several $\mu m$, also known from quantum dots [39, 40], are still large in comparison with the lattice constant of the material. The band structure of a semiconductor is therefore only weakly changed when being spatially confined compared to the bulk material [41]. This assumption allows investigating solely changes in the envelope part of the wave function caused by the confinement potential and is called envelope function approximation. However, in spatially confined structures, surface polarization effects may play a role due to the different dielectric constants of the material and its surrounding. This becomes in particular important when investigating Rydberg excitons, which are quasiparticles bound by the three-dimensional Coulomb interaction.
Quantum confinement effects arise as soon as the spatial confinement is comparable to the quantum object’s Bohr radius. Rydberg excitons have Bohr radii up to μm size. This allows to confine them in so-called mesoscopic structures, the dimension of which is large compared to the lattice constant but comparable to the exciton Bohr radius (see figures 1(b), (c)).

We want to confine a whole Rydberg exciton into a quantum well, and expect large energy shifts of this giant quantum object. In excitons the Coulombic electron–hole attraction gives rise to bound states of the relative motion of the exciton. The excitonic bound levels in quantum wells are, in many respects, analogous to the Coulombic impurity bound states, meaning that the electron and hole relative motion is described by a Hamiltonian which is similar to that of an impurity [42]. We intuitively associate an extra kinetic energy with the localization of a particle in a finite region of space, i.e. the impurity binding energy increases when the quantum well thickness decreases.

1.3. Quantum confined Rydberg excitons

In mesoscopic cuprite slabs surrounded by air or vacuum, the potential barrier accounts for 2.98 eV, which is given by subtracting the Rydberg binding energy (2.17 eV) from the work function energy of electrons in cuprite to air (5.15 eV). This finite potential well energy can, however, be treated as an infinite potential barrier due to the fact that the linear dimension of the confinement exceeds the lattice constant of the semiconductor [41].

In the following, we will focus on the weak confinement regime, where the confinement acts only on the center-of-mass motion of the exciton, i.e. the envelope of the Bloch functions, and does not interfere with the relative motion of the electron–hole pair. Here, the Rydberg exciton binding energies are larger than the confinement effects. In contrast, in the strong confinement limit, the picture of an exciton would be destroyed, as one would then treat electron and hole separately with their individual motions being quantized. In this case, the confinement energy dominates over the Rydberg exciton binding energy.

2. Methods

In order to calculate the energy shifts a Rydberg exciton experiences when being confined in a quantum well, we perform potential well calculations for the center-of-mass coordinate of a Rydberg exciton in a cuprous oxide quantum well (see figure 1(d)). The quantum well consists of a cuprite slab that is extended many micrometers in the x and y direction but confined to a few hundreds of nanometers only in the z direction. It is surrounded by air or vacuum. Usually, this quantum mechanical problem is not separable due to the confined geometry. In particular, the Coulomb interaction, causing the electron and hole relative motion, is always of three-dimensional nature and depends on the relative electron–hole distance. However, for large quantum wells (weak confinement regime) the confinement or perturbation acts only on the center-of-mass coordinate and is assumed to not disturb the relative motion. Then a separation into relative and center-of-mass coordinates is possible as an approximation.

3. Results

3.1. Electron states for infinite potential barriers

When a quantum object, such as an electron, is spatially confined in one dimension, it gains potential energy $V(z)$, which can be expressed in the Schrödinger equation as:

$$-\frac{\hbar^2}{2m} \nabla^2 + V(z) \psi(x, y, z) = E \psi(x, y, z).$$  \hspace{1cm} (7)

The electron wave function can be separated into $\psi(x, y, z) = \phi(x, y) \varsigma(z)$, which allows for solving the Schrödinger equation via the separation ansatz:

$$-\frac{\hbar^2}{2m} \nabla^2 \phi(x, y) = E_\phi \phi(x, y)$$  \hspace{1cm} (8)

and

$$\frac{\hbar^2}{2m} \frac{\partial^2}{\partial z^2} + V(z) \varsigma(z) = E_\varsigma \varsigma(z).$$  \hspace{1cm} (9)

Equation (8) yields the particle kinetic energy $E_\phi = \hbar^2 (k_x^2 + k_y^2)$, which is comparable to equation (2) for the exciton, while equation (9) determines the particle’s quantized energy eigenvalues due to the quantum confinement

$$E_\varsigma = \frac{\hbar^2 \pi^2}{2m} \left( \frac{j}{L_c} \right)^2,$$  \hspace{1cm} (10)

with $j$ being the quantum state index in the quantum well and $L_c$ the well width. The quantized bound states energies increase with decreasing quantum well width and are proportional to the quantum state index $j^2$.

3.2. Weakly confined Rydberg excitons in cuprite quantum wells

Following the calculation scheme from the previous section, we calculate the Rydberg exciton energies in a cuprite quantum well with quasi-infinite potential well barrier

$$V_0(z_{e,h}) = \begin{cases} 2.98 \text{ eV}, & |z_{e,h}| > L_c/2 \\ 0 \text{ eV}, & |z_{e,h}| < L_c/2 \end{cases}.$$  \hspace{1cm} (11)

The Hamiltonian describing this problem is given by

$$H = -\frac{\hbar^2}{2m_e} \nabla_e^2 - \frac{\hbar^2}{2m_h} \nabla_h^2 + V_{\text{Confinement}} + V_{\text{Coulomb}}$$

$$= -\frac{\hbar^2}{2m_e} \left( \frac{\partial^2}{\partial x_e^2} + \frac{\partial^2}{\partial y_e^2} + \frac{\partial^2}{\partial z_e^2} \right)$$

$$- \frac{\hbar^2}{2m_h} \left( \frac{\partial^2}{\partial x_h^2} + \frac{\partial^2}{\partial y_h^2} + \frac{\partial^2}{\partial z_h^2} \right)$$

$$+ V_0(z_{e,h}) - \frac{e^2}{\epsilon_0 |r_e - r_h|},$$  \hspace{1cm} (12)
and reads in relative and center-of-mass coordinates:

\[
H = -\frac{\hbar^2}{2m_\epsilon} \frac{\partial^2}{\partial z^2} - \frac{\hbar^2}{2m_e} \frac{\partial^2}{\partial z_e^2} - \frac{\hbar^2}{2M_o} \left( \frac{\partial^2}{\partial X^2} + \frac{\partial^2}{\partial Y^2} \right) \\
- \frac{\hbar^2}{2m_\epsilon} \frac{\partial^2}{\partial z^2} + \frac{\partial^2}{\partial z_e^2} + V_0(\zeta; \hbar) - \frac{e^2}{\varepsilon_0 r},
\]

(13)

Applied to the exciton wave function this yield a series of bound exciton lines at energy positions:

\[
E_n^{2D} = E_z - \text{Ry}^* \frac{1}{(n - \delta_n)^2} + \frac{\hbar^2 \pi^2}{2m_r} \left( \frac{j}{L_z} \right)^2.
\]

(14)

This is similar to equation (1) but with an additional quantized energy term \( \Delta_{\text{conf}} = \hbar^2 \pi^2 j^2 / (2m_r L_z^2) \) due to quantum confinement in one dimension, with \( j \) being the quantum state index and \( L_z \) being the quantum well width.

### 3.2.1. Rydberg exciton diameters versus quantum well sizes

From quantum dots it is known that for confinements smaller than 0.4 \( \cdot \) \( a_B \), excitons break up [41]. On the other hand, for well widths \( L_z \approx 4 \cdot a_B \), the energy shift should be most pronounced. Furthermore, we investigate weakly confined Rydberg excitons, i.e. Rydberg excitons in quantum wells of sizes \( L_z \gtrsim 4 \cdot r \). As the Rydberg exciton radius increases with increasing principal quantum number \( n \), we define \( \Delta_L = L_z - 2r \), as the confinement parameter of interest. This allows to include the \( n \) dependence of the confinement potential for a certain confinement length \( L_z \). We calculated the Rydberg P-exciton radii in cuprite according to \( r = 0.5 \cdot a_B \left( \frac{3n^2 - 1}{l(l + 1)} \right) \), with \( n \) and \( l \) being the principal and angular momentum quantum number respectively, and \( a_B = a_B^{Cu_2O}(3n^2 - 1(l + 1)) \), with \( a_B^{Cu_2O} \) Bohr radius, \( m_e \) electron mass, \( m_r \) reduced mass of exciton in \( Cu_2O \), \( \varepsilon^{Cu_2O} \) permittivity. The confinement parameter \( \Delta_L \) for four different confinement lengths \( L_z \) is plotted in figure 2 together with the exciton diameter \( d = 2r \) for excitons in different principal quantum number states \( n = 2 \ldots 20 \). The weak confinement regime holds in 2 \( \mu \)m wide quantum wells for Rydberg excitons in principal quantum number states up to \( n = 16 \), in 1.5 \( \mu \)m wide wells up to \( n = 13 \), in 1 \( \mu \)m wide wells up to \( n = 11 \), and in 500 nm wide wells up to \( n = 8 \). The higher the principal quantum number state, the larger the exciton, the smaller the remaining space in the quantum well and, thus, the smaller the confinement parameter \( \Delta_L \).

### 3.2.2. Rydberg exciton energy shift

Quantum confinement along one dimension causes an increase in potential energy of the confined Rydberg exciton dependent on the confinement parameter \( \Delta_L \), the confinement quantum state \( j \) and the quantum object mass \( m_r \). We show in figure 3 the calculated energy blue-shifts \( \Delta_{\text{conf}} = \hbar^2 \pi^2 j^2 / (2m_r L_z^2) \) experienced by Rydberg excitons in cuprite quantum wells for the lowest and third excited quantum state \( j = 1 \) and \( j = 3 \) respectively, and for four different well widths \( L_z \in \{0.5; 1; 1.5; 2\} \mu m \). The data are only shown within the weak confinement regime, which applies for Rydberg excitons with up to a different amount of principal quantum number \( n \) for different quantum well sizes \( L_z \) (see also figure 2).

For both, the lowest \( (j = 1) \) and third excited \( (j = 3) \) quantum state index, and for all different well widths \( L_z \) shown here, the energy shift \( \Delta_{\text{conf}} \) increases with increasing principal quantum number \( n \). This increase in energy is absolutely larger and steeper the smaller the well widths. For the lowest quantum state index \( j = 1 \), \( \Delta_{\text{conf}} \) accounts for up to 14 \( \mu \)eV, while for the third excited quantum state index

![Figure 2.](image)

![Figure 3.](image)
\( j = 3 \Delta_{\text{conf}} \) reaches values of up to 140 \( \mu \text{eV} \), which is one order of magnitude larger.

### 3.3. Strongly confined Rydberg excitons in cuprite quantum wells

Subject of this paper is the weak quantum confinement of Rydberg excitons in cuprite quantum wells. The relevant structures are of several hundreds of nanometers to a few micrometers in size, which can be procured straightforwardly using focused ion beams. Furthermore, we want to investigate a single, giant quantum object—the Rydberg exciton. In the strong confinement regime, the confinement energy would exceed the Coulomb energy and thus the binding energy of the exciton. In this case, electron and hole are confined separately in their respective confinement potentials. We believe that the following considerations regarding the strong confinement regime might be of interest for the reader.

#### 3.3.1. Exciton binding energy in the strict 2D limit

The 3D Rydberg P-exciton energy is given by \( E_n = E_g - E_b = E_g - \text{Ry}^* / (n - \delta_p)^2 \), with \( E_g \) band gap energy, \( \text{Ry}^* \): Rydberg constant for excitons in cuprous oxide, \( n \): principal quantum number, and \( \delta_p = 0.23 \): quantum defect for P-excitons [43]. In strictly two dimensions, the Rydberg exciton binding energy \( E_b \) becomes modified into \( E_b^{2D} = \text{Ry}^* / (n - 1/2)^2 \) [44]. This implies that the lowest 2D exciton energy \( (n = 1) \) has a magnitude four times larger than the 3D exciton ground state, when neglecting the quantum defect: \( E_b^{2D} - E_b = 4E_b \). Thus, the exciton ground state is farther away from the bandgap in 2D and the 2D Bohr radius \( a_b^{2D} = a_b^{3D} / 2 \) is half as big as the 3D value. The excitonic resonances as well as the exciton binding energies are stronger in 2D. Interestingly, the absorption strength decreases in this situation more rapidly with \( n \). The transition from 3D to 2D would cause exciton energy shifts of even a few meV:

\[
\Delta^{2D} = E_n - E_n^{2D} = E_g - (E_g - E_b^{2D}) = -E_b + E_b^{2D} = -\frac{\text{Ry}^*}{(n - \delta_p)^2} + \frac{\text{Ry}^*}{(n - 1/2)^2}.
\]

The exciton binding energy in three dimensions decreases rapidly with \( n \). So does the binding energy in two dimensions as well, however, at some larger values. The difference of both, defined as the energy shift \( \Delta^{2D} \), thus, follows the same trend. Note that a larger Rydberg binding energy implies a smaller Rydberg exciton energy as the binding energy (\( \text{meV}\)) is subtracted from the band gap energy (\( \text{eV}\)) in order to yield the exciton energy \( E_n = E_g - E_b \). Therefore, the effect the 2D confinement will have on the total exciton energy will be a red-shift toward lower energies.

#### 3.3.2. Influence of the permittivity of the surrounding material outside the quantum well

In the case of a very narrow quantum well, the permittivity inside and outside the well is different. The Coulomb interaction between electron and hole in an exciton is of three-dimensional character and, thus, not squeezed inside the well, but occurs primarily outside the well with less effective screening [45]. The binding energy would then become:

\[
E_b^{2D} = \left( \frac{2\varepsilon}{\varepsilon_1 + \varepsilon_2} \right)^2 \left( \frac{\text{Ry}^*}{(n - 1/2)^2} \right),
\]

with \( \varepsilon = 9.8 \): cuprous oxide permittivity and \( \varepsilon_1 = \varepsilon_2 = 1 \): air permittivity surrounding the narrow well structure. This would imply another increase in binding energy of almost two orders of magnitude:

\[
\left( \frac{2\varepsilon}{\varepsilon_1 + \varepsilon_2} \right)^2 = \left( \frac{2\varepsilon 9.8}{2} \right)^2 = (9.8)^2 = 96.04 \approx 10^2.
\]

### 4. Discussion

The quantum confinement inhibits free motion and, thus, influences the kinetic energy of the quantum object. Only discrete values are allowed, leading to a series of quantized states [46]. Confined to a quantum well, Rydberg excitons gain energy, so they experience an energy blue-shift. Within the weak confinement regime, this energy shift accounts for a few and a few tens of \( \mu \text{eV} \) for the lowest and third excited quantum state index, respectively.

The energy shifts are controllable via the three parameters principal quantum number \( n \), quantum state index in the quantum well \( j \), and quantum well width \( L_z \) over a wide range. Such controllable energy shift could be used for realizing quantum technologies using Rydberg excitons in cuprous oxide [2]. In order to enlarge the range over which the energy can be shifted, one could go to higher confinement, meaning a more tight confinement along one dimension (intermediate or strong confinement regime in 2D).

The conditions for the strong confinement regime become, as shortly discussed in section 3.3, more complicated. Strictly speaking, for a very strong exciton confinement, electron and hole become quantized separately, so the quantization energy dominates over the Coulomb interaction energy and we cannot speak of an exciton any more. In order to get a feeling for how the energy shifts would develop when going towards the intermediate regime \( (L_z \approx 2r) \), we applied our weak confinement model to excitons in this intermediate confinement regime. The resulting energy blue-shifts \( \Delta_{\text{conf}} \) are depicted in figure 4 for the lowest quantum state index \( j = 1 \), for different well widths \( L_z \), and in dependence on the principal quantum number \( n \).

The transition from the weak to the intermediate regime is smooth. As expected, the energy blue-shifts become significantly larger the narrower the quantum wells, and account for up to several tens of meV. In the strong confinement regime, the electron and hole confinement energies would exceed the exciton binding energy \( \text{Ry}^* \approx 96 \text{ meV} \).
the top of the diagram. The energy shifts in dependence on the principal quantum number \( n \) and for seven different well widths \( L_z \). The strong confinement regime begins where \( \Delta_{\text{conf}} \approx E_0 = 96 \text{ meV} \); this is at the top of the diagram.

Figure 4. Energy shifts in \( \mu \text{eV} \) due to quantum confinement \( \Delta_{\text{conf}} \) for the lowest quantum state index \( j = 1 \), for weak (\( L_z \gg 4r \), squares) and intermediate (\( 2r < L_z < 4r \), circles) regimes. The energy shifts are shown in dependence on the principal quantum number \( n \) for four different well widths \( L_z \). The strong confinement regime begins where \( \Delta_{\text{conf}} \approx E_0 = 96 \text{ meV} \); this is at the top of the diagram.

5. Outlook

Higher quantum confinements can also be reached by confining a quantum object in two or three dimensions. This can be realized by confining Rydberg excitons into cuprite quantum wires or quantum dots (see figure 1(b)). In such structures the energy shift caused by the confinement geometry reads:

\[
\Delta_{\text{conf}}^{1D} = \frac{\hbar^2 \pi^2}{2m_r} \left( \frac{j_r^2}{L^2} + \frac{j_y^2}{L^2} + \frac{j_z^2}{L^2} \right) \xrightarrow{L_z \ll L_x=L_y} 2 \cdot \Delta_{\text{conf}}^{2D}
\]

and

\[
\Delta_{\text{conf}}^{0D} = \frac{\hbar^2 \pi^2}{2m_r} \left( \frac{j_r^2}{L^2} + \frac{j_y^2}{L^2} + \frac{j_z^2}{L^2} \right) \xrightarrow{L_z \ll L_x=L_y} 3 \cdot \Delta_{\text{conf}}^{2D}.
\]

The blue-shift could, thus, be enhanced by a factor of 2 and 3 compared to the quantum well structures. It remains, however, unknown how the Rydberg binding energy would change in such structures.

Recent advances in focused ion beam milling using Au\(^+\) ions (Raith IonLine) make it possible to fabricate tailored quantum wells with widths in the hundreds of nm range, as shown in figure 5. Therefore one should in principle be able to weakly confine experimentally Rydberg excitons into quantum wells. The difficulty remains in that the well interface needs to be very flat, to not disturb the crystal lattice, its symmetry, and thus the exciton formation. The energy shifts could be measured in absorption or by pump-probe spectroscopy. This gives for the first time the opportunity to probe such large quantum objects inside the confined geometry of quantum wells.
